## 1. Sanity check

#### Sanity check on accuracy:

A random classifier would label an instance with the correct class with a probability of 1/10, as there are 10 classes (with an almost balanced number of instances). That's why I would expect that a trained model outperforms its random classifier.

The number of TP, FP, FN, and TN values can be calculated for a random classifier more precisely, and hence also its accuracy. And, one can apply Fisher's exact test to compare the predictive performance results of the random classifier with the trained model. However, it is not necessary to do it here, as one can safely say that the random classifier labels an instance with the true class with a probability of 1/10. And, this is basically the threshold a trained model's predictive performance needs to pass.

It is visible that all models whose hyperparameter configuration and predictive performance results are given below outperform their random classifier.

#### Sanity check on loss:

Plugging the probability value discussed above into the cross-entropy loss formula, it can be yielded that the value is log(10).

That is, the expected value of the cross-entropy loss for a random classifier is around log(10) = 1.

# 2. Grid Search

### 3. Best Models' Evaluation and Discussion

The hyperparameter configuration with the best performing validation accuracy for each k-layered network is highlighted in the corresponding table.

#### 3.1. Best configuration for 1-Layered Network

The following is the hyperparameter configuration to produce the highest accuracy value and the performance results for a 1-layered network.

batch size: 32,

Learning rate: 0.0005, Optimizer: Adam,

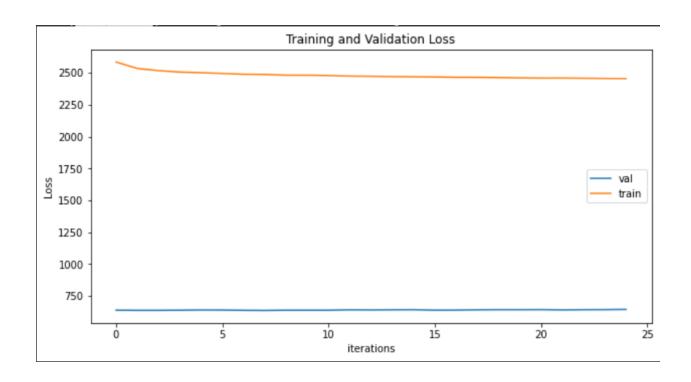

Epoch: 25

Validation accuracy: 30.000%

Validation loss: 2.0155

Test accuracy: 28.770%

The following graph shows the validation and loss errors:

#### 3.2. Best configuration for 2-Layered Network

The following is the hyperparameter configuration to produce the highest accuracy value and the performance results for a 3-layered network.

batch size : 64, Learning rate: 0.001, Optimizer: Adam,

Number of neurons in the first layer: 512

Activation function after the first layer: hardswish

Epoch: 25

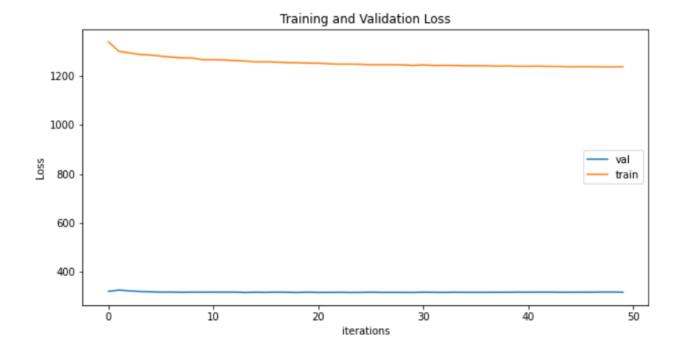

Drop out rate: 0.5

Validation accuracy: 30.010%

Validation loss: 2.0202

Test accuracy: 29.780%

The following graph shows the validation and loss errors:

#### 3.3. Best configuration for 3-Layered Network

The following is the hyperparameter configuration to produce the highest accuracy value and the performance results for a 3-layered network.

batch size : 64, Learning rate: 0.001, Optimizer: Adam,

Number of neurons in the first layer: 512 Number of neurons in the second layer: 216 Activation function after the first layer: tanh Activation function after the first layer: tanh

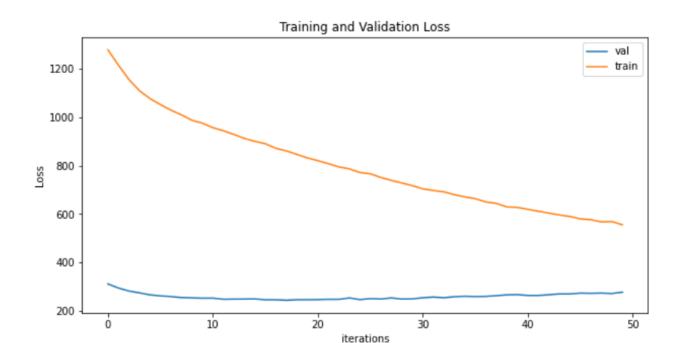

Epoch: 50

Validation accuracy: 45.600%

Validation loss: 1.7321

Test accuracy: 44.820%

The following graph shows the validation and loss errors:

Based on Vapnik's Structural Risk Minimization, the models fail to generalize, ie, fail to learn, or overfit when the training loss decreases too much and the validation loss starts to increase. That is, after that point of training the model, it memorizes rather than learning, so it fails on unseen data, that's why it fails to generalize.

The graphs drawn show both the validation and training losses obtained. Ideally, the point where the validation loss starts to increase and keeps increasing while training loss decreases is where we should stop training to avoid overfitting. However, this is not what we wee in the above graphs. That is, it seems that there is a need for more number of epochs of training, ie, models are underfit. However, especially 1 and 2-Layered networks seem that they are not complex enough to learn, or it would take too much time for them to learn. To illustrate, one can look at the highlighted rows in grid search tables, and deduce that with more epochs their loss does not change much. In fact, they start to perform worse with more number of epochs. In particular, the best models for 1 and 2 layered networks are trained on 25 epochs, and it can be seen in the same graphs, looking at rows that are 3 below, that with more epochs (keeping all the other hyperparameter configurations same), their predictive performance gets worse. That's why, the point where I stopped training seems not to be coherent with Vapnik's Structural Risk Minimization.

#### 4. Performance Metric

Accuracy is merely a measure of how many instances were correctly classified. That's why it is a feasible metric to evaluate cases where the misclassified items are not that important. For example, if we are to trying to find the faulty systems based on some data, and finding the faulty ones are so important that even the "potentially-faulty ones" are of major importance, we might overlook some False Positives. However, the extreme case for what is explained might be just labeling every instance as positive, which is obviously not an acceptable performance. In fact, if there is a class imbalance, and the number of positive instances is truly higher than that of negative ones, it is possible for a classifier to just label all instances as positive and get extremely high accuracy results. Merely trying to maximize the accuracy value might lead to such a case. That is, hyperparameter optimization assessing other metric would be different than these.

The class imbalance is not the only reason which makes the accuracy value not a feasible metric. For example, if the interest in finding the negative ones is as high as or more than that in the positive ones, we better check other metrics, such as precision.

For this dataset, I first checked the number of instances for each class and did not observe a class imbalance problem. If it were the case, I would have checked their weighted accuracy values as well. However, since accuracy, in the end, is a metric that is only concerned about the correctly labeled instances, it still can be tricked easily. There are other metrics that are commonly used to assess the predictive performance such as F1-score, however, it might be biased towards the class with the higher number of annotations. One metric commonly used for such cases is matthews correlation coefficient (MCC).

#### 5. Other Questions

# 5.1. What are the advantages/disadvantages of using small/big learning rates?

Learning rate is a hyperparameter to decide how much the weights are updated based on the calculated error. The neural networks' learning algorithm is based on gradient descent which is to find the minimum error. Although it is guaranteed that the algorithm will converge to a minimum, it might get stuck at some global minima too, which is undesirable. That is, choosing a large learning rate, the algorithm is susceptible to converge to a local minimum, and produce poor performance. Whereas, choosing a small learning rate makes the algorithm run slower, ie, it takes too many epochs for it to converge.

# 5.1. What are the advantages/disadvantages of using small/big batch sizes?

Batch size is a hyperparameter to determine the number of samples to be propagated through the network before its weights are updated. For example, for stochastic gradient descent algorithm has a batch size = 1. Choosing a large batch size makes the network train faster, as it can be optimized for parallel processing. However, although the reason for it is not well known, choosing a really large batch size causes overfitting, ie, prevents the model from generalizing well.
